SINGLE-STEP PROCESSING

BACKGROUND

This invention relates to programmable processors.

5 A programmable processor, such as a microprocessor for
a computer or a digital signal processing system, may
execute instructions far more rapidly than a human being
can execute them. Consequently, when a processor makes an
error, which may occur for several reasons, the error
10 usually occurs so quickly that a human cannot directly
observe what led to the error. Various techniques,
generally called "debugging," may be employed to track down
the source or sources of the error.

DESCRIPTION OF DRAWINGS

15 Figure 1 is a block diagram illustrating an example of
a pipelined programmable processor.

Figure 2 is a schematic illustrating an example
execution pipeline.

20 Figure 3 is a flowchart illustrating a process for
single-step debugging.

Figure 4 is a flowchart illustrating another process
for single-step debugging.

Figure 5 is a flowchart illustrating a process for selecting one of the single-step debugging processes.

DETAILED DESCRIPTION

5 Figure 1 is a block diagram illustrating programmable processor 10 coupled to main memory 16 and input/output device 22. Processor 10 includes control unit 12, execution pipeline 14 and input/output interface 18 and may be, for example, a digital signal processor.

10 Control unit 12 may control the flow of instructions and data through pipeline 14. For example, during the processing of an instruction, control unit 12 may direct the various components of pipeline 14 to decode the instruction and perform the corresponding operation
15 including, for example, writing the results back to main memory 16.

 Control unit 12 may include exception handler 20, which may hold addresses of pre-defined instructions to be processed in pipeline 14 when an exception is raised.
20 Control unit 12 may also include control register 25, which stores data related to control functions. Control bits 23A and 23B in control register 25 comprise information related to single-step debugging techniques, as will be described

in more detail below. The state of control bits 23A and 23B can be sensed by pipeline 14 via two-bit bus 24.

Main memory 16 may store information such as instructions and data. Main memory 16 may comprise static random access memory (SRAM), dynamic random access memory (DRAM), flash memory or the like. Processor 10 may include components not shown in Figure 1, such as an instruction cache. A user may communicate with processor 10 via one or more input-output devices 22, such as a keyboard, mouse, stylus or other pointing device, coupled to processor 10 by way of interface 18. Processor 10 may communicate with a user via one or more input-output devices 22, such as a display screen or printer, coupled to processor 10 by way of interface 18.

Figure 2 illustrates an example pipeline 14. Pipeline 14, for example, may have five stages: instruction fetch (IF), instruction decode (DEC), address calculation (AC), execute (EX) and write back (WB). Instructions may be fetched from memory 16 or from an instruction cache during the first stage (IF) by fetch unit 30 and may be decoded by instruction decode unit 32 during the second stage (DEC). At the next clock cycle, the results may be passed to the third stage (AC), where data address generators 36 calculate any memory addresses to perform the operation.

During the execution stage (EX), execution unit 38 may perform the specified operation such as, for example, adding or multiplying two numbers. During the final stage (WB), the results may be written back to main memory 16 or
5 to data registers 40.

Pipeline 14 typically includes stage registers 42 that are used as temporary memory storage elements and may be used to pass results and other information from stage to stage. In addition to registers 42 and data registers 40,
10 pipeline 14 may include additional memory elements or registers for holding instructions, addresses, data or other information.

Pipeline 14 ordinarily processes instructions in a substantially concurrent manner, with several instructions
15 in pipeline 14 in different stages. For example, while one instruction is in the WB stage, another instruction may be in the EX stage, and a further instruction may be in the AC stage. In some circumstances, however, it may be advantageous to process one instruction, then examine the
20 states of processor 10 and/or the contents of the various registers before completing the processing of the following instruction. Processing instructions in this fashion is called "single-step debugging" and may be desirable, for example, during debugging. Debugging may involve, for

example, executing an instruction and examining the contents of memory elements such as registers before executing the next instruction. Single-step debugging and examination of memory elements may allow a user to

5 understand whether an error is hardware-based or software-based, to identify problems in the hardware or software, and to observe the interaction among software instructions. Debugging may take place during development of processor 10, before processor 10 is incorporated into a product.

10 Debugging and may also be performed after processor 10 is incorporated into a product.

When a user wants to begin single-step debugging, the user may give a command to processor 10 by way of an input-output device 22, such as a keypad. Processor 10 may

15 support different modes of single-step debugging, and the user may further specify the desired manner.

One mode of single-step debugging, illustrated in Figure 3, employs taking an exception following each instruction. In general, an exception suspends normal

20 program execution, while allowing the instruction ahead of the exception in pipeline 14 to complete execution. Upon initiating this mode of single-step debugging (50), control unit 12 directs fetch unit 30 to fetch a single instruction, which is processed through the stages of

pipeline 14 (52). When the instruction reaches the WB stage, pipeline 14 raises an exception (54). The exception may be a specially defined single-step exception, and may be defined not to execute error-handling routines.

5 In response to the single-step exception, control unit 12 typically cancels instructions in the pipeline 14 (56) and routes control to exception handler 20 (58). Exception handler 20 includes addresses of pre-defined instructions to be processed in pipeline 14 when a single-step exception
10 is raised (60). Such instructions may include sensing the processor states and outputting information about the states via input/output interface 18 (62), sensing the register contents and outputting the contents (64), and clearing the exception (66). The instructions may be
15 adapted to sense particular register contents or particular processor states. In addition, outputting information may include sending information to input/output device 22, such as a printer or display screen, and may also include writing the information to main memory 16. The
20 instructions (60) shown in Figure 3 are exemplary. Other instructions may be executed, such as dumping contents of main memory 16 or a cache, or saving and restoring processor states.

When the exception is cleared (66) and other instructions of the exception handler have been executed, control unit 12 may continue the single-step debug process (68) by sending another instruction through pipeline 14 (52), which results in another exception upon completion (54). The instruction to be sent is typically one that was previously sent through pipeline 14 but was cancelled (56) before execution was completed, due to the previously handled exception. The user may also choose to terminate single-step operation (70).

Single-step debugging by taking single-step exceptions may be useful for some purposes, and is usually fast and inexpensive, and usually requires no additional hardware. This technique may not be suitable for all purposes, however. For example, this technique may not be effective for debugging the exception handler itself. In addition, the technique may not be effective for debugging protected system resources such as high-level event-handling routines. High-level event-handling routines may have, for example, higher priorities than the exceptions, and consequently may take precedence over the exceptions and may prevent the exceptions from being raised.

Another approach to single-step debugging is to enter a high-level operating mode, such as emulation mode, and

feed each instruction individually to pipeline 14.

Generally speaking, a processor may have many modes of operation, such as a user mode and a supervisory mode,

which will be discussed in more detail below. Emulation

5 mode is a mode of operation adapted for operations such as

debugging. Typically, in emulation mode pipeline 14

fetches instructions from an emulation instruction

register, rather than from main memory 16 or an instruction

cache. Pipeline 14 also typically reads and writes data

10 from an emulation data register rather than from main

memory 16 or a data cache.

Figure 4 is a flow chart illustrating an example process for single-step debugging, including processor 10

operating in emulation mode. Typically, processor 10

15 begins in a mode other than emulation mode, such as user

mode or supervisor mode. Processor 10 may have more or

fewer modes of operation than the user, supervisory and

emulation modes. The user mode of operation is generally the most frequent form of operation. Applications running

20 on processor 10 usually invoke the user mode of operation.

In user mode, certain processor functions or system

resources are deemed out of bounds and cannot be accessed.

Attempted access of a restricted function or resource

generally results in an error-type exception. Supervisor

mode, by contrast, represents a higher priority mode of operation, in which all processor functions and resources are available. Emulation mode is usually a higher priority mode of operation than supervisor mode, allowing debugging
5 of system resources that may otherwise be out of bounds. Consequently, single-step debugging in emulation mode may be preferable when system resources are to be debugged.

To begin single-step debugging (80), an instruction is sent through pipeline 14 (82). When the instruction
10 reaches the WB stage, pipeline 14 raises an emulation event (84). Emulation mode may be invoked in different ways for different processor architectures, such as by applying a signal to a particular processor port or by executing software designed to invoke emulator mode. Once in
15 emulation mode, high-level processor functions and resources are available, and inputs and outputs to processor 10 are regulated. Control unit 12 typically cancels instructions in the pipeline 14 (86) and routes control to an emulation service routine (88). The
20 emulation service routine includes instructions that may include sensing the processor states and outputting information about the states via input/output interface 18 (92) and sensing the register contents and outputting the contents (94). Outputting information may include sending

information to an output register or to input/output device
22, and may include writing the information to main memory
16. Emulation mode generally is terminated by a "return"
instruction, which returns processor 10 to the state in
5 which it was operating before invoking emulation mode and
includes the address of the next instruction to be fetched
(96). Typically, return from emulation mode after each
step (96) is automatic, so continued single-step debugging
(98) may involve each single-step operation being
10 separately commanded. If no command to enter emulation
mode is given, the single-step operation terminates (100).

Control of single-step debugging can be regulated in
many ways. An exemplary method to control single-step
debugging, illustrated by Figure 5, is to employ one or
15 more control bits, which automatically result in the
generation of the single-step debugging operations and
instructions. Setting one or more control bits may be
detected by logic that may trigger an exception or an
emulation event. In exemplary processor 10 shown in Figure
20 1, two control bits 23A and 23B are shown as stored in
control register 25 and are made available to pipeline 14.
Control bits 23A and 23B may be stored elsewhere and may be
stored in any kind of memory element. Many processor
architectures, however, support control registers.

Use of two control bits 23A and 23B allows flexibility in single-step debugging. Control bits 23A and 23B can be set in four distinct logical configurations: '0-0,' '0-1,' '1-0' and '1-1.' The configurations may be assigned four
5 different results. For example, the '0-0' configuration may be the norm, indicating that no single-step debugging of any form is to occur. Setting control bits 23A and 23B (110) comprises changing the bits from the '0-0' configuration to some other configuration. The mode of
10 single stepping is a function of control bits 23A and 23B (112). The '0-1' configuration, for example, may result in single-step debugging by entry into emulation mode (118), regardless of whether processor 10 is in user mode or supervisor mode. Similarly, the '1-0' configuration, for
15 example, may result in single-step debugging by taking exceptions (116), regardless of whether processor 10 is in user mode or supervisor mode. Finally, the '1-1' configuration may, for example, result in selection of the form of single-step debugging depending upon the current
20 operating mode of processor 10 (114). When processor 10 is operating in user mode, the '1-1' configuration may cause processor 10 to single-step by taking exceptions (116), but when processor 10 is operating in supervisor mode, the '1-1' configuration may cause processor 10 to single-step by

entering emulation mode (118). The results obtained by following the techniques shown in Figure 5 are summarized in Table 1.

Control bits	Operating Mode	Single-step Debugging Mode
'0-0'	User	None
'0-0'	Supervisor	None
'0-1'	User	Emulation
'0-1'	Supervisor	Emulation
'1-0'	User	Exception
'1-0'	Supervisor	Exception
'1-1'	User	Exception
'1-1'	Supervisor	Emulation

Table 1

A number of embodiments of the invention have been described. For example, methods of single-step debugging have been described, by taking an exception after each instruction or by placing the processor in an emulation mode. The processor may be implemented in a variety of systems including general purpose computing systems, digital processing systems, laptop computers, personal digital assistants (PDA's) and cellular phones. In this context, the single-step debugging techniques discussed

above may be readily used to test the system before or
after a customer sale. In such a system, the processor may
be coupled to a memory device, such as a FLASH memory
device or a SRAM device, that stores an operating system
5 and other software applications. These and other
embodiments are within the scope of the following claims.
